Breaking Badly: The Currency Union Effect on Trade[†]

Douglas L. Campbell[§] New Economic School Aleksandr Chentsov[‡] New Economic School

June, 2020

Abstract

As several European countries debate entering, or exiting, the euro, a key policy question is how much currency unions (CUs) affect trade. Recently, Glick and Rose (2016) estimated that CUs increase trade on average by 100%, and that the euro has increased trade by 50%. In this paper, we find that other major geopolitical events correlated with CU switches drive the large estimated impact of CUs on trade. We find that these estimates are sensitive to intuitive controls and to dynamic specifications. Overall, we estimate that the impact of CUs on trade is often indistinct from zero, depending on the specification and controls.

JEL Classification: F15, F33, F54 Keywords: Euro, Currency Union Effect, Gravity Estimation

[†]. Special thanks are in order for the comments we have received presenting an early draft to students in our International Macroeconomics course at both the undergraduate and graduate levels at the New Economic School, particularly to Dmitry Limin, and to the Riga BICEPS conference. We would also thank anonymous referees and editors for their helpful feedback. All errors are our own.

As several European countries debate entering, or exiting, the euro, a key policy question is how much currency unions (CUs) affect trade. In recent years, for example, the Euro has continued to grow in size, with the addition of Slovakia (2009), Estonia (2011), Latvia (2014), and Lithuania (2015), despite a mixed Euro Zone economic record. While questions of politics and identity drive the enlargement of the Euro Zone, another driver is that these countries want to foster closer trade ties with Western Europe.

And, according to recent research, Glick and A. Rose (2016) (hereafter GR) and Saia (2017), Euro membership has led to a large increase in trade.¹ Running a differencein-difference regression using panel directional export data with rich fixed effects and a dummy for CUs, GR estimate that, overall, CUs double trade, while the Euro has increased trade by 50%. This research suggests that the benefits of joining a CU are real, and perhaps large enough to outweigh the detrimental effect of ceding control of one's monetary policy (other benefits of the Euro notwithstanding). GR also find that not all CUs increase trade – the Eastern Caribbean Currency Union *decreased* trade by 80%, while US dollar unions have no effect. Such heterogeneous effects beg explanation.

Rose himself has written that the CU effect seems implausibly large.² We agree, since an estimated effect size of even 50% would be much larger than what Irwin (1998) finds for the Smoot-Hawley tariff, despite the fact that a CU would seem to have a modest effect on actual trade costs. GR define a CU when two countries have money that is interchangeable at a 1:1 par for an extended period of time. Yet, it is unclear why a 1:1 par value for a currency would have a large, positive impact on trade, but not, for example, a 1.2:1 par value. A priori, it seems more plausible that the estimated effect is driven by a special relationship among countries which decide to share a CU, or rather, a major geopolitical event causing countries to decide to dissolve their CUs, as these relationships are meant to be forever and do not end randomly.

To understand what kind of endogeneity might be driving the result, consider the case of India and Pakistan, whose bilateral trade is plotted in Figure 1. At first glance,

^{1.} Glick (2017) argues for a Euro effect 25% smaller than GR (2016), while Glick and A. K. Rose (2015), which pre-dated GR (2016), found that the impact of the Euro on trade is sensitive to using a PPML specification. Other recent papers that find a positive impact include Kunroo et al. (2016), Camarero et al. (2014), Felbermayr et al. (2017), Gunnella et al. (2015), Gil-Pareja et al. (2008), Martínez-Zarzoso and Johannsen (2017), Rotili et al. (2014), Esteve-Pérez et al. (2020), Chen and Novy (2018) and Kopecky (2019), while Macedoni (2017) finds evidence consistent with the Euro reducing trade costs. Saia (2017) finds that UK trade with the Euro Area would have been 16% higher had the UK joined the Euro. However, using the same synthetic control method, he also finds that had the UK joined the Euro, its trade with several non-Euro Area countries would have been 18% higher. We interpret this second exercise as a placebo test, and thus conclude that given the treatment effect is smaller than the placebo, Saia's results are comparable to that which we find.

^{2.} Rose once wrote "I have always maintained that the measured effect of a single currency on trade appears implausibly large..."

it may seem like a textbook case in which the dissolution of a CU crippled trade, since bilateral trade fell by 99.8%. However, the dissolution occurred simultaneously with the outbreak of a brutal border war over the legacy of partition, while political relations between the two countries remain frigid to this day.³ Other examples include former French and Portuguese colonies, which often achieved independence after major conflicts that sometimes coincided with communist takeovers.

Figure 1: Indo-Pakistani Trade: A Textbook Case of the CU Effect or Endogeneity? Notes: This figure plots bilateral trade over time for India and Pakistan, one of the CUs in the GR (2016) data. These countries exited a shared currency union in 1965, after which trade plummeted. However, this was the same year as the Indo-Pakistani War of 1965 following Operation Gibraltar, a secret Pakistani operation to infiltrate Jammu and Kashmir to foment rebellion against Indian rule. Relations between these countries remain tense.

Endogeneity and third factor causality might also have been factors leading to spurious large estimates of the euro on trade. The history of European integration, from the Coal and Steel Community, to the Fall of the Berlin Wall and the formation of the EU, implies that there are other reasons, aside from the Euro, why European trade has increased over time.

In this paper, we subject the findings of GR (2016) to a number of robustness checks. First, we plot residualized pre- and post-treatment trends for CU entrances and exits for the sample of country-pairs with at least 10 years of data before and after a switch (ex-EMU). We do not not find evidence of an effect for this particular sample. For Western-European EMU countries, we find that trade had begun increasing in the 1950s, too early to have been caused by anticipation effects. We also find that the increase in trade among euro members since 1999 is almost exactly equivalent to the increase for all

^{3.} See Prasad, The India-Pakistan War of 1965: A History (2011).

Western European countries (or EU countries). For Eastern Europe, we find that the evolution of trade with EMU countries is similar for those countries which eventually joined the EMU and those that did not. Lastly, we find that trade fell by 86% prior to the breakup of CFA Franc countries, but that trade actually *increased* after dissolution.

Next, we control for a small set of relevant omitted variables in a panel regression setting with directional exports as the dependent variable, and importer*year, exporter*vear, and country-pair FEs (*i.e.*, with the same data and FEs as GR). For example, in the case of Western European euro countries, we include a dynamic EU control, creating a set of annual dummies for trade between all Western European EU countries (or, alternatively, all Western European countries, including those not in the EU). For Eastern European countries, we use a number of other Eastern Bloc countries that did not join the euro during our sample period as a control group, and create an Eastern Europe*euro*year interactive dummy. This is a way to control for the end of the Cold War on trade between Eastern and Western Europe. For the UK's trade with countries that used the pound, we select other prior British colonial possessions as the control group. In addition, we include a simple dummy variable for hostile colonial breakups. This is a small fraction of the CU switches in the sample, or of colonial breakups, but it also proves influential as a control. For the CFA Franc, we include a simple time trend for country-pairs that eventually experienced dissolutions. Even with these controls, we find a borderline significant CU effect of about 11%. However, this estimate is probably sensitive to further controls for omitted variables (or multi-way clustering), as we also show it is driven in part by the sample with missing data coterminous with a CU switch.

Third, realizing that both trade and currency union status are highly persistent, and given the evidence that trade shocks leave persistent changes in trade patterns, we explore several simple dynamic models. Using log changes in trade as the dependent variable, we find that trade actually grows more slowly under a CU, although the effect is insignificant. If we run a lagged dependent variable model instead, we continue to find a large and significant impact of CUs on trade. This effect is still sensitive to the controls discussed above, however. A 65-year panel in this case helps to reduce Nickell-type biases.

Lastly, we show that the CU effect on trade is also not robust when we use a Poisson Pseudo-maximimum Likelihood specification instead of a log-linear model.

This literature began with Rose (2000), who found that CUs triple trade. This sounded suspiciously large to some, and so subsequent literature set out to dampen the effect (*e.g.*, Nitsch (2002)).⁴ However, Glick and A. Rose (2002), using a larger dataset,

^{4.} Additionally, Persson (2001) and Pakko and Wall (2001) followed Rose's (2000) original paper but

found that CUs double trade in a time-series setting even when including country-pair fixed effects.⁵

Nevertheless, doubts remained.⁶ Nitsch (2005) found no impact for CU entries; Klein (2005) found no trade effect of dollarization episodes; and Bomberger (2003) found that a simple time trend eliminated the effect for the UK colonial sample (one-fifth of the total switches in GR 2002). Thom and Walsh (2002) noted that many CU exits had obvious omitted variables such as wars of independence and communist takeovers. Berger and Nitsch (2008) considered early evidence on the euro and argued that, given the long history of European trade integration, the key question is whether the euro increased trade relative to the long-run trend. They found that it did not.⁷ Klein and Shambaugh (2006) found that hard currency pegs have a much smaller impact on trade than currency unions, and that indirect pegs – which are much more likely to be random – have no effect on trade at all.

Campbell (2013) drew on these insights, showing that the apparent impact of CUs on trade was sensitive to: (a) excluding the CU observations coterminous with other major political events or missing data, (b) including a UK colony time trend, and (c) clustering the standard errors. He also found it possible to arrive at point estimates of CUs on trade that are *negative* and insignificant by controlling for trends. However, GR (2016) responded with a data set extended to 2013 (an additional 16 years of data), that included 423 bilateral CU switches compared to 136 in GR (2002).⁸ In addition, several other recent prominent papers have found evidence for large CU effects, including Saia (2017) and Larch et al. (Forthcoming), even if the latter finds no effect for the euro

predated GR (2002), and greatly reduced or eliminated the estimated impact on smaller datasets.

^{5.} The result appeared robust enough that in 2005, Harvard's Jeff Frankel called Rose's discovery of the large apparent impact of CUs on trade the most significant finding in International Macroeconomics in the preceding ten years. On the other hand, worried about the endogenous nature of CUs, Alesina et al. (2002) and Barro and Tenreyro (2007) opted for geographic instrumental variable approaches, finding that CUs actually increase trade on a 14-fold and a 7-fold basis.

^{6.} For example, Baldwin (2006) wrote an influential overview of the literature, providing several reasons why the larger estimates of the impact of CUs on trade were unreliable, and concluding that the euro might have increased trade by a still-sizeable 5-10%. Additionally, Bun and Klaassen (2007) include dynamic controls and shrink the CU impact to a precisely estimated 25%.

^{7.} Santos Silva and Tenreyro (2009) also found no effect of the euro on trade. In a meta-analysis, Havránek (2010) found systematic evidence of publication bias for the euro studies, as well as a mean impact of just 3.8% versus over 60% for earlier non-euro episodes. De Sousa (2012) argued that the impact of CUs on trade has dampened over time due to improvements in financial technology, yet there was also little measured impact in the prewar era according to Wolf and Ritschl (2011). López-Córdova and Meissner (2003) find mixed support.

^{8.} The authors should further be commended for plotting pre- and post-treatment trends, and for adopting a new specification with one-directional exports as the dependent variable while controlling for importer*year and exporter*year interactive fixed effects. They should also be credited for creating a much larger data set of CU observations, and for sharing this data set publicly, to our advantage.

specifically.

This paper is the first to test whether omitted variables and dynamic specifications discussed in Campbell (2013) drive the apparent large impact of CUs on trade using GR's (2017) much larger data set (we study four times as many CUs as in Campbell (2013)). In addition, we also study the euro period, implement superior Importer*Year and Exporter*Year FEs in a specification using directional exports, and do not drop the observations coterminous with war or missing data – all distinct from (Campbell (2013)). While some other studies also find no effect of the euro (Nähle (2015), Tykkyläinen (2012), and Figueiredo et al. (2016)⁹, Rose (2017) argues in a meta-analysis that the reason that some euro studies find smaller, no, or even a negative impact is that they use either fewer countries or fewer years. By contrast, we show that the key is really controlling for other key aspects of European integration, since we use the same data and estimation strategy as GR (2016). In an important contribution, Larch et al. (Forthcoming) show that the apparent impact of the euro is smaller and insignificant when using a PPML estimator, although they find that other CUs are still significant. We show that neither the euro nor non-Euro CUs are robust even using log-linear OLS, Glick and Rose's preferred estimator.¹⁰

In the rest of the paper, we first describe the data and methodology, and then implement our empirical approaches: (1) plotting pre- and post-treatment trends, (2) static panel regressions, and (3) dynamic panel regressions.

1 Data

We use the same data set provided by Glick and A. Rose (2016), with trade data from the IMF's *Direction of Trade Statistics* (DOTs) between 1948 and 2013. Population and real GDP data come from the World Bank's *World Development Indicators*, supplemented with the Penn World Table v7.1 and the IMF's *International Financial Statistics*. Data on regional trade agreements come from the World Trade Organization. For consistency, we also use the same definition of currency union provided by GR: "that money was

^{9.} In a useful test, Martínez-Zarzoso (2019) finds no evidence in the aggregate of increased trade between African countries pegged to the Franc and EMU countries after the formation of the Euro. Mika and Zymek (2017) focus on late entrants with data from 1992-2013 using a PPML estimator (used also by GR (2016b)), and argue that the problem is log-linear OLS. We show that even using log-linear OLS, the euro effect is not robust.

^{10.} In the appendix, we do implement our panel regressions using PPML (Table 19) and find, not surprisingly, that the results are wildly different from OLS as well as for each CU individually. Only one of the eight major CUs has a consistently positive impact on trade, and one has a consistently negative impact.

interchangeable between the two countries at a 1:1 par for an extended period of time, so that there was no need to convert prices when trading between a pair of countries". Currency union classification were taken by GR from the IMF – see GR (2016) for details.

Table 1 compares the number of CU switches in GR (2002) vs. GR (2016), for both the euro and non-euro observations. GR (2002) had a total of 136 CU switches, 108 of which came from exits. Only 66 of these switches remained, however, after excluding those switches with obvious major geopolitical events which overshadow changes in CU status, with missing trade data before or after a CU switch, or with colonial histories. In GR (2016), this sample increases to 647 in terms of one-way trade flows (each country pair is in the data twice). Thus, we have a much larger sample of CU switches than Campbell (2013) had to consider the impact of CUs on trade. Table 2 sums up switches and observations by disaggregated CU. The largest CU in terms of separate country-pairs was actually the UK pound, followed by the EMU.

	GR 2002	GR 2016 (One-directional)
Entrants with Time Series Variation in Data	28	372
Exits with Time Series Variation in Data	108	556
Total Switches with Time Series Variation in Data	136	901
Missing Data Immediately Before or After Switch	26	209
War or Other Major Geopolitical Event (Using Campbell 2013 definition)	26	49
Switches ex Missing Data or War:	88	647
Switches ex Missing Data, War, or Former Colonial Relationship:	66	447
Total Country Pairs:	11077	34104
% of Country-Pairs with CUs:	1.86	3.46
Total Observations:	$218,\!087$	879,794
% of Observations with CUs:	1.45	1.95
Time Period	1948 - 1997	1948-2013

Table 1: Number of Changes in Currency Union Status

In the first column, the numbers of switches with time series variation represent the number of switches for country-pairs with non-missing GDP product and bilateral trade for at least one observation both in and out of a CU. For the second column, the only required non-missing variable is the (log) export value.

Currency Union	GR 2002	GR 2016 (One-Directional)	Observations (2016)
EMU	0	270	5024
CFA Franc	53	99	15062
ECCA	5	11	3062
Australia	2	6	1446
UK	25	308	14672
French Franc (pre-euro)	3	26	1448
Indian Rupee	6	28	2280
US Dollar	4	77	5236
Portugal	4	22	860
Other CUs (ex-Portugal)	21	68	3744
Total	123	915	52834

Table 2: Changes in CU Status by Currency Union

This table plots the number of country-pairs with at least one CU status switch (note that one country-pair might have more than one switch, and have belonged to more than one CU, so that the totals here will not necessarily add up to the above) with time series variation in data for disaggregated currency unions, requiring the same non-missing variables as for Table 1.

2 Methodology

2.1 Plotting Pre- and Post-Treatment Trends

First, to understand how changes in CU status affect trade dynamics, we plot the preand post-treatment trends. We run the following panel regression:

$$ln(X_{ijt}) = \alpha_{ijt}^{EnterCU_k} + \eta_{ijt}^{ExitCU_k} + \beta Z_{ijt} + \lambda_{it} + \psi_{jt} + \gamma_{ij} + \epsilon_{ijt}.$$
 (2.1)

Where $ln(X_{ijt})$ is log directional exports from country i to country j at time t, $\alpha_{ijt}^{EnterCU_k}$ is a set of dummies for an exporter-importer country pair for specific years before and after a specific CU entrance, and $\eta_{ijt}^{ExitCU_k}$ is another set of dummies for years before and after a CU exit. We also include: (1) λ_{it} , exporter*year interactive FEs, (2) ψ_{jt} , importer*year interactive FEs, and (3) γ_{ij} , country-pair FEs. We use only CUs with 10 years of data before and after a switch to ensure we have a consistent sample.

This allows us to visualize the dynamic effects of joining or leaving a CU. This is important, as we might expect that it takes several years for the full effect a CU to be realized, in which the estimate in 2.2 would be downward biased. We plot pre- and post-treatment trends separately for the euro and for the CFA franc, two of the largest CUs in our sample, in part to help motivate controls in the panel regressions that follow.

2.2 Panel Regression Methodology

2.2.1 Benchmark Methodology

Following GR 2016, we estimate a gravity equation with rich importer-year and exporteryear FEs, and bilateral country-pair FEs, using one-way directional exports as the dependent variable:

$$ln(X_{ijt}) = \alpha C U_{ijt} + \beta Z_{ijt} + \lambda_{it} + \psi_{jt} + \gamma_{ij} + \epsilon_{ijt}, \qquad (2.2)$$

where X_{ijt} is the average of exports from i to j reported by i and the same variable reported by country j at time t. CU_{ijt} is a 0/1 dummy for CU status in a given year, λ_{it} are exporter-year interactive FEs, ψ_{jt} are importer-year interactive FEs, δ_{ij} are country-pair FEs, and Z_{ijt} include other controls. We cluster at the country-pair level (each country-pair appears twice for a given year), in the interests of conservatism. (In the online appendix, we show that the standard errors only grow when we cluster in multiple dimensions.)

Equation 2.2 identifies the impact of a CU from the time series variation. It asks how much one country will export to another on average after they join, or before they leave, a currency union, relative to all exports for the exporting country and relative to all imports for the importing country. If two countries enter into a CU precisely because they trade more, the country-pair fixed effect will control for this. The two main problems with this methodology are that CUs are potentially endogenous, and secondly that it ignores dynamics. If two countries form a CU, not just because they trade more, but because their trade intensity is increasing over time, then this method will bias up the results. We might instead want to ask if they are trading more relative to their prior trend. However, even if they were trading more relative to trend (we will see that they do not), sharing a CU is likely to be a proxy for good, or at least stable, political relations. CU dissolutions are likely to be caused by other major geopolitical events that dwarf the impact of a change in CU status for their implications on trade volumes, such as warfare or the ethnic cleansing of one's neighbors. Lastly, when two countries form a CU, trade might actually increase for a few years before arriving at a new steady state. In that case, a static approach using a 0/1 CU dummy variable might bias the true effect downward.

2.2.2 Additional Controls

In order to mitigate endogeneity and omitted variable bias, we propose a series of controls which are essentially designed to provide more specific, and intuitive control groups for each given CU. These include:

1. For Western Europe, we create a control group by including annual dummies for all exports within country-pairs who are both members of the EU. This includes three nations in the EU but not in the euro. Thus, we ask, how much did trade within euro members increase relative to their trade with other EU members that did not join the euro? (One could do this instead for all countries in Western Europe, including the three nations we have data for that are not in the EU, but in practice the results are not statistically distinct from what we report.)

2. For Eastern European euro entrants, we include other nearby countries which did not join the euro in the control group. Thus, we ask, what is the impact of joining the euro for EE countries relative to other EE countries that did not join the euro? (The non-Euro EE sample includes Latvia, Lithuania, Hungary, the Czech Republic, and Croatia, countries that either joined the euro after the sample ends or did not join.)

3. We include UK colony*year FEs. Thus, we ask, what was the level of trade for those countries who left a UK CU relative to the UK's trade with other colonies? This control is motivated by the observed decaying trend in trade between the UK and its former colonies over time, and the decline in trade between those colonies themselves.

4. We also include a Common UK colonizer*year interactive trend. For each former UK colony, we control for the trend in its trade with other former UK colonies. Trade intensity among this sample also decays over time, although less strongly than trade with the UK itself.

5. For the CFA countries, we include a simple time trend for countries that had CFA Franc exits. Thus, the variable takes the value zero for country pairs that were never part of the CFA Franc, and equals the "year" variable for country pairs that did have a CFA Franc exit.

6. We include a separate colony dummy for those countries that had had some form of colonial relationship, but then experienced hostilities. We include in this dummy pairs of countries, such as India and Pakistan, that had a common colonizer, but then had hostilities at the end of the colonization period, using the onset of war as the event date. It has been observed (e.g., Head et al. (2010)) that the evolution of trade for countries with hostile versus amicable breakups varies greatly. Note that hostile colonial breakups constitute a small fraction of the total CU dissolutions, and the timing of the colonial

breakup does not always coincide exactly with the recorded CU dissolution.

In addition, we already know from Campbell (2013) that the Glick and A. Rose (2002) estimates of CUs were driven in part by CU switches coterminous with missing data. Thus, we also do an exercise where we separate the CU switches that had continuous data before and after a CU switch from CUs that had missing data, and compare the results.

2.3 A Dynamic Gravity Regression

Theoretically, the existence of large sunk costs, learning-by-doing, or consumer habits would imply that "the gravity equation" should be a dynamic gravity equation, where trade is a function of GDP, current trade costs, and also the past history of trade costs (see Campbell (Forthcoming) and Campbell (2010) for proofs). A "dynamic" form of a gravity model, a lagged dependent variable (LDV) model, is:

$$ln(X_{ijt}) = \sum_{k=1}^{K} \rho_k ln(X_{ij,t-k}) + \alpha C U_{ijt} + \beta Z_{ijt} + \lambda_{it} + \psi_{jt} + \gamma_{ij} + \epsilon_{ijt}$$
(2.3)

where the Zs are other controls, and this time we have included lagged dependent variables. In this specification, we effectively allow the short-run and long-run impacts of a CU to be different. Note that, typically, the main problem this specification faces is a type of Nickell (1981) bias, as a LDV model with panel FEs induces a well-known bias. However, this bias disappears in long panels. In this case we have 65 years of data, although admittedly with gaps. Nickell found, that for reasonably large values of T, the limit of $(\hat{p}-p)$ as $N \to \infty$ will approximate to $-(1+\rho)/(T-1)$. This implies the standard Nickell bias on the order of .03 – relatively modest in the context of the CUs and trade literature, where 100% effect sizes are not uncommon. One alternative to this would be to simply run with the dependent variable in first differences. In this version, we would be testing whether trade grows faster for countries when they are in a CU vs. when they are not.

2.4 Poisson Pseudo-Maximum Likelihood (PPML)

An alternative to gravity in logs is to estimate a Poisson Pseudo-Maximum Likelihood (PPML) regression. The main benefit of this method is that we no longer need to drop zero observations for exports, as we do when we take logs. Thus, we run the following

PPML regression:

$$X_{ijt} = exp(\alpha CU_{ijt} + \beta Z_{ijt} + \lambda_{it} + \psi_{jt} + \gamma_{ij}) + \nu_{ijt}$$

$$(2.4)$$

Where now X_{ijt} is the level of exports from country i to j at time t (no log), and we include the same set of importer*year, exporter*year, and country-pair FEs as before. We then also add in our controls from 2.2.2.

2.5 Synthetic Control Method

Another option would be to implement a synthetic control method. Saia (2017) implements such an approach, and conducts a counterfactual analysis for the UK implying that trade would have been higher had Britain joined the Euro. However, the Stata package Saia used, the "synth" package, requires a balanced panel, and is computationally intensive, which may be why he uses a sample of just nine countries (we use 213 in our panel). Saia formed synthetic control groups based on absolute nominal trade levels (not logs) pre-euro, and thus effectively does not control for GDP or trends in total imports/exports. In the online appendix, we replicate Saia, and then show what happens when we use a slightly different, theoretically-motivated choices of weights, and design our synthetic control to predict the trade-to-GDP ratio rather than the level of trade. We find starkly differing results. Given that Saia's sample is rather small, and doing this method justice would probably require a full paper, we leave this exercise to the Online Appendix.

3 Results

3.1 Results: Plotting Pre- and Post-Treatment Trends

3.1.1 Pre- and Post-Treatment Trends for the Entire Sample

We implement regression (2.1) and plot the pre- and post-treatment trends for the full sample of CUs (before and after a CU exit) in Figure 2, and also before and after a CU entrance for the non-EMU group. We find that trade did appear to fall about 20% after dissolution, but we also find that this amount was not statistically significant. Ten years after dissolution, the effect was closer to -2%, although this effect was small relative to the estimated standard errors, and a higher level than trade had been for most of the CU period. For the entrants, trade also increases after the formation of the CU, but the effect is small relative to estimated clustered standard errors. In both cases, it appears there is too much noise to make any hard conclusions. Note that, in this case, our model with importer*year and exporter*year FEs removes much of the troubling pre-trends found by GR (2016) when they do a similar exercise for a model that only included country-pair FEs.

Figure 2: Impact of CU Exits and Entrances

Notes: Panel (a) shows the evolution of trade before and after CU exits using equation 2.1. Panel (b) shows the evolution of trade before and after entrances, ex-EMU. Both use only CUs with full data at least 10 years before and after changes in CU status.

3.1.2 Pre-and Post-Treatment Trends for the Euro

Since the euro represents 29% of the bilateral switches in CU status in our data, we next focus on this CU in some detail. Given the different histories of Western Europe and the former Warsaw Pact entrants to the euro, we pick control groups for Eastern and Western Europe separately.

The differences between these two regions are stark. Among Western European countries, integration in the post-World War II period began in earnest with the European Coal and Steel Community signed at the Treaty of Paris in 1951, the beginning of the European Economic Community in 1958, the Schengen Agreement in 1985, and the formation of the EU in 1993, which itself updates and adjusts its rules frequently. Thus, the formation of the euro can be viewed as merely one step of a decades-long economic integration within Europe. In addition, trade was disrupted during World War II, and thus, as Glick and Taylor (2010) and Campbell (2010) argue, it naturally took decades for historical trade patterns to be reestablished, while lingering wartime animosities might also have depressed trade between, for example, France and Germany for decades. In Eastern Europe, the Russian Revolution (1917), the end of WWII and the formation of the Warsaw Pact effectively cut off most trade between Eastern Europe and Western Europe. The collapse of the Soviet Union and the opening of former Warsaw Pact countries to trade with the west was another seminal event which naturally would take time to play out in full.

In Figure 3(a) we plot the dummies from equation 2.1 for before and after the formation of the Euro, and compare them to a slight modification with annual dummies for EU members, and for all countries in Western Europe.¹¹ Here, note that the UK, Denmark, and Sweden were EU members during this time, but not members of the euro, and that Norway, Switzerland, and Iceland are also in Western Europe but are not members of the EU. We include country-pairs with at least 40 data points to ensure that the results are not driven by changes in the sample over time, but the results do not change materially when we use all available data.

What we find is that trade did increase substantially after the formation of the euro, but trade among EU and all European countries changed by almost exactly the same amount compared to 1998, the last year prior to the Euro. However, on the other hand, in this specification, the euro countries experienced less of a positive pre-trend than EU countries, or all of Western Europe. This suggests that, relative to trend, the euro might have actually had a positive impact on trade. However, one can only arrive at this conclusion by including pre-trends as controls, and this difference turns out not to be statistically significant.

In Figure 3(b), we test for statistical significance of the impact of the euro vs. other countries in Western Europe by running equation 2.1 with all non-Western European countries removed from the control group. It shows that there was in fact slightly less trade between Euro-Area countries relative to trade with the rest of Europe in 2013 as compared with 1998, the last year pre-euro, but that this magnitude is much smaller than the measured standard errors. Bergin and Lin (2012) point out that there could be anticipation effects with the euro, but in this particular specification, trade intensity increases from 1950 to 1970, likely too early to have been related with the euro. If one were to run the Glick-Rose specification with data from 1965 instead, the estimated euro effect would also shrink (see the Additional Appendix).

A referee suggests measuring both the EU and euro effect as a dummy of years before or after entry, which also clearly makes a core of sense (countries joined the EU

^{11.} Thus, we run: $ln(X_{ijt}) = \alpha_t * I_{ij}^{EU} + \beta Z_{ijt} + \lambda_{it} + \psi_{jt} + \gamma_{ij} + \epsilon_{ijt}$. where $\alpha_t * I_{ij}^{EU}$ is a year*EverEU interactive FE. Then we run a third regression replacing EU countries with all Western European bilateral pairs.

(b) Impact of Euro, W.Europe as Control

Figure 3: The Euro Effect by Year, vs. the EU and all of Western Europe Notes: Panel (a) shows the evolution of export intensity of countries which eventually joined the euro vs. the rest of Europe, using equation 2.1, and all available data. Panel (b) plots the impact of the Euro over time while limiting the control group to Western Europe.

at different times). We compare the results in Figure 7, and find that they are not materially different (the upward pre-trend in trade among Euro Area countries before 1970 is somewhat mitigated). The euro does not appear to have significantly boosted trade. This referee also suggested looking at the effect on trade between non-euro and euro country trade, and there, too, taking a similar approach, we do not see a strong case that the euro increased trade with the outside world. There is even a hint of a negative impact relative to trend (see Figure 9).

In Figure 4(a), we plot the trade trajectory for the Eastern European euro entrants - Slovenia, the Slovak Republic, and Estonia – that joined the euro late (2007, 2009, and 2011). Note that the upward trend in trade long predates the period when these countries joined the euro.

Next, in Panel B, we use as our control group other Eastern European countries that did not join the euro, or which joined much later. Thus, we choose Latvia, Lithuania, Hungary, the Czech Republic, and Croatia as our control countries. What we find is that much of the trend is gone, and that, compared with 2007, trade actually declined in most years thereafter. However, we also find very large standard errors, and so in the end we conclude that we cannot say much other than that the significant impact we get in panel (a) is gone. Thus we conclude that the case for a large euro effect on trade for the Eastern European countries is sensitive to the control group, and Figure 4(a) suggests it would be sensitive to a control for trends in the post-Soviet period.

Figure 4: Eastern European Euro Entrants

Notes: Panel (a) shows the evolution of the trade intensity of countries which eventually joined the EMU from 2007 to 2011 – Slovenia, the Slovak Republic, and Estonia – and prior EU entrants using equation 2.1, and using the full sample as controls. Panel (b) adds in a control group using annual dummies for trade between a larger number of Eastern European countries, some of whom joined the euro later and others not at all – Latvia, Lithuania, Hungary, the Czech Republic, and Croatia.

3.1.3 The CFA Franc

We also plot pre- and post-treatment trends for the CFA franc ("Colonies Françaises d'Afrique") in Figure 5, since this is the third largest CU in our sample, and the dynamics in this union are particularly interesting. What we see is that in the last 15 years before exit, trade declined by 86% (=exp(-2)-1). After the dissolution, if anything, it appears that trade appears to have increased. This is a key example of how a simple dummy variable approach can be misleading, and also why one might want to control for dynamics. What we propose is a simple time trend for this sample of countries.

3.2 Main Regression Results

Next we estimate equation 2.2 and present the panel regression results in Table 3. In Column (1) and Column (2), we benchmark the results from Glick and Rose's Table 5 (right panel). We confirm their estimated coefficient of .34 for CUs overall (implied trade impact of over 40%) and a t-score of nearly 19, seemingly leaving little doubt as to the trade-creating powers of CUs. Note that each disaggregated CU ostensibly has a widely varying impact on trade. If we interpret this as a causal relationship, then it would be a major puzzle: the Eastern Caribbean CU apparently reduced trade by 81% (=exp(-1.64)-1), while the French franc apparently increased trade by a staggering

Figure 5: Impact of CFA Exits and Entrances

Notes: Panel (a) shows the evolution of trade before and after exits into the CFA Franc using equation 2.1. Panel (b) shows the evolution of trade before and after entrances.

139%. If, however, endogeneity, omitted variables, and the non-random nature of CU formation and dissolution drive these effects, then the findings are simply noise rather than a puzzle. Put simply, the wide variation in the apparent impact of individual CUs is the result of the different historical factors that drove the formation/dissolution of each individual CU. In addition, the highly significant t-scores may suggest the presence of spatial and autocorrelation in the errors.

In Column (3), we add in clustered standard errors at the country-pair level to address serially correlated errors. This addition causes the errors to increase substantially. For example, the error on the EMU increases from .021 to .061. The Australian dollar and the Indian rupee unions are now no longer statistically significant. Note that if we were to three-way cluster, by the importer country, exporter country, and year, as Cameron et al. (2011) and Egger and Tarlea (2015) suggest, the standard errors would rise further for some CUs. For example, the error for the EMU would rise to .14. Clustering by country-pair should address autocorrelation but would leave our errors biased downward in the presence of spatial correlation, which some recent studies have found is nearly ubiquitous in econometric work using spatial data (*e.g.*, Kelly (2019).

In Column (4), we add in our controls discussed in Section 2.3. Now we find that the French franc, the CFA franc, and the euro no longer have a significant effect, while the estimated coefficient for the British pound has shrunk. How do each of the controls separately impact the coefficients? In general, the coefficients for an individual CU are only impacted by controls for that specific CU - e.g., the euro controls do not, in practice, affect the coefficients or standard errors for the other CUs. The only exception is the hostile colonial breakup dummy, which lowers the estimated impact for the French franc, the Indian rupee, and for the "Other CUs", but has scant effect on the other coefficients. (In the online appendix, Table 21, we add in the controls one by one.) In Column (5), we again use the controls as in Column (4) and aggregate all the non-euro CUs into one variable. In Column (6), we report the aggregate results, which we find are borderline significant at 90%. Lastly, in Column (7), we separate the CU switches coterminous with missing data from the others. In doing so we find a point estimate of .087 for those switches without missing data, versus a much larger impact for those CUs with missing data coinciding with a switch. One could interpret this in a number of ways: either that CUs have a larger impact on trading pairs for which trade (and trade-reporting agencies) is fragile, or that perhaps the data is missing for these country pairs for some other reason that might be correlated with why the CU collapsed (for example, a war or ethnic cleansing episode).

Note that we have not even controlled for all known sources of endogeneity. For example, we have done nothing to control for war generally or for ethnic cleansing episodes. Bangladesh and India shared a CU for two years in the wake of Bangladesh's liberation war with Pakistan (which India joined), but much of the high trade volume recorded during those two years was more likely due to military and economic assistance than to having a common fix to the British pound. Such examples are difficult to control for systematically. Researchers working in this area may consider dropping the small number of influential CU switches that coincide with obvious major geopolitical events.

3.3 Dynamic Gravity Regressions

Next, we move to our dynamic regressions in Table 4, using the Lagged Dependent Variable (LDV) model presented in Equation 2.3. First, for easy comparison, we repeat the GR benchmark estimate of the CU effect in Column (1). In Column (2), we run the same regression in log changes. This time, we find that exports actually grow more slowly when two countries share a CU – a rather stark difference. This conclusion holds up when we add in our controls from section 2.3.

Next, in Column (4), we run the version with LDVs. We go out to the third lag because we find that the fourth lag is not significant. This time the impact of CUs is still highly significant, with a coefficient of .14, implying a short-run impact of roughly 15% and a long-run impact of 43.5%, the latter of which is a bit higher than what

Table 3: How Robust is the CU Impact on Trade?

*p < 0.1, ** p < 0.05, *** p < 0.01. The dependent variable is the average of log exports from country 1 to country 2 reported by each. Each regression includes country-pair and importer*year and exporter*year interactive fixed effects. Other controls, including a dummy for 'regional trade agreements' and 'currently a colony' or 'same country' are omitted for space. Columns' (1) and (2) replicate Table 5 of GR. Column (3) clusters the errors by country-pair. Column (4)-column (7) includes the controls from Section 2.2.2: (a) EU*Year FEs, (b) EE*Euro*Year FEs, (c) UK Colony*Year FEs, (d) Common UK Colony year trend, (e) CFA Exit*year trend, (f) hostile colonial breakup dummy (=1 for still a colony).

the static regression framework suggests. However, when we include our controls from section 2.3 in column (5), the coefficient on CUs shrinks to .025 and loses significance. One concern is that the combination of an LDV and panel FEs biases our coefficient of interest. One way to mitigate this is with a longer (average) panel. Thus, in column (6), we limit our sample to country-pair combinations with at least 40 years of data and an average panel length of 56 years, and the coefficient on CUs shrinks even further. Still, there are two caveats: the FEs in this regression will induce a (relatively small) bias, and the first-differenced regression is likely slightly over-differenced given the FEs. Omitting some of the FEs would also reduce the bias and degree of over-differencing (a regression of exports on lags of itself without FEs would a sum of lagged coefficients of .97, very close to a unit root) but would not materially alter our conclusions.

Table 4: Dynamic Models

*p < 0.1, **p < 0.05, ***p < 0.01. The dependent variable in the first two columns is bilateral trade, the log change in bilateral trade in the third column, log bilateral exports in columns (3) and (4), and the log change in bilateral exports in column (6). Each regression includes country-pair FEs (CPFEs). Column (1) benchmarks the baseline estimate from GR (2002), absent year FEs. Column (2) benchmarks the results (absent trend controls) from Campbell (2013), and includes year FEs. Columns (3) and (5) benchmark the CPFE results from GR (2016). Columns (4) and (6) omit the CUs in which switches were coterminous with war or missing data, and also includes other intuitive controls.

3.4 PPML Results

Lastly, in Table 5 we present our results for the PPML regressions. In the first two columns, we present the benchmark results with none of our added controls. In the second two columns, we add in the controls and show that the results change. In particular, the results for CUs overall go from a coefficient of .13 (implying an impact of about 14%), and highly significant, to a coefficient of .07 (implying an impact of about 7%), and no longer statistically significant. Once again, the estimates differ wildly across CUs, but our end conclusion is the same: the CU effect is not robust.

Table 5: PPML

*p < 0.1, ** p < 0.05, *** p < 0.01. Standard errors clustered at the country-pair level. The dependent variable is the level of directional exports (not the log) from country i to j at time t. Each regression includes country-pair, importer*year, and exporter*year FEs. Columns (3) and (4) add in the same controls as discussed in Section 2.2.2: (a) EU*Year FEs, (b) EE*Euro*Year FEs, (c) UK Colony*Year FEs, (d) Common UK Colony year trend, (e) CFA Exit*year trend, (f) hostile colonial breakup dummy (=1 for still a colony).

4 Conclusion

We estimate the impact of CUs on trade and find a noisy zero. Previous large estimated impacts of CUs on trade (such as GR (2016)) were driven by third factors and are sensitive to intuitive controls and to dynamic and PPML specifications. Pre- and posttreatment trends overall are not supportive of a CU effect on trade. When we adopt a dummy-variable matching approach to compare the evolution of trade between countrypairs that have a CU switch and intuitive control groups, we find that the apparent impact of CUs on trade shrinks to more plausible levels, albeit imprecisely estimated with single-way clustered standard errors. We also find that the apparent CU effect is sensitive to dynamic specifications. A limitation of our study is that even we do not believe we have removed all sources of endogeneity or controlled for all possible omitted variables in our panel regressions, so that our final results – insignificant in the dynamic or PPML specifications, or at best borderline significant in a static log specification – could still be biased in either direction. That the estimated CU effect is much larger (and significant) for CU switches coterminous with missing data also suggests that there may be other important omitted variables, such as political alliances, and various aspects of trade policy such as tariffs and quotas, which are difficult to control for with such a large data set. Also, we report results when clustering in a single direction in the interests of being conservative. Yet, we cannot guarantee that we have removed all the sources of correlation in the errors, and when we multi-way cluster, the estimated errors tend to increase.

The finding of a large impact of currency unions on trade deserves to be a textbook case-study of endogeneity and omitted variable bias in empirical international trade. This literature also shows the importance of Bayesian priors since our initial reason for skepticism was that the magnitude of the measured effect – a doubling of trade - is simply too large relative to related results in the literature, and large relative to intuition. For example, Irwin (1998) finds that the Smoot-Hawley tariff was estimated to have decreased trade by 4-8%. How plausible is it that CUs have an impact 12-20 times larger? This is particularly so since Klein and Shambaugh (2006) found that indirect currency pegs – more likely to be random – are also uncorrelated with higher trade flows. We believe our results are reasonable since there is no theoretical or intuitive reason to expect that there is anything special about a 1:1 par value. Our findings can also help explain why different CUs appeared to have wildly different impacts on trade: the results may have simply been spurious. Finally, note that there is nothing in this analysis to rule out a positive (or negative) effect size of 1-2%, or even 10%, given that one estimated standard deviation from zero in our static regression equates to roughly a 6% increase in trade. The conclusion is rather that the previous large, highly significant estimates are fragile.

5 Appendix

Figure 6: Currency Unions, Wars, Missing Data, and Trade Collapses

Notes: Panel (a) shows the evolution of trade over GDP between India and Pakistan, who dissolved a currency union as the same time as a brutal border war. In panel (b), Kenya and Tanzania ended their currency union amidst the Liberation War and overthrow of the Dictator Idi Amin. In panel (c), Portugal and Angola ended their currency union after a bloody civil war resulted in a communist takeover. In panel (d), it can be seen that after Guinea and Mauritania ended their currency union in 1968, trade was not even recorded again for another two decades.

Figure 7: The Euro Effect by Year (Europe as Control Group)

Notes: Panel (a) shows the evolution of directional exports of countries which eventually joined the euro using the rest of Europe as a control, using equation 2.2. All Western European countries with at least 40 observations are included. Panel (b) also controls for a dynamic EU effect using dummies for years before and after EU accession.

Figure 8: The Euro Effect by Year (Europe as Control Group)

Notes: Panel (a) shows the evolution of directional exports of countries which eventually joined the euro using the rest of Europe as a control, using equation 2.2. All Western European countries with at least 40 observations are included. Panel (b) also controls for a dynamic EU effect, this time using a separate dummy for each year for a country pair where both were EU members (regardless of whether it was before or after joining). This slightly different method of controlling for a dynamic EU effect yields similar results as in Figure 7. We thank a referee for suggesting.

(a) One in Western Europe as Control

(b) One in Europe as Control

Figure 9: Did the Euro Increase trade with Rest of the World?

Notes: Panel (a) shows the evolution of directional exports of countries which eventually joined the euro and compares it to the evolution of exports for country-pairs with exactly one country using the euro, using all country-pairs with at least one country in Western Europe as controls. Panel (b) uses as a control group all country-pairs in which one country eventually became a member of the EU. Note that these regressions do not (cannot) control for importer*year and exporter*year FEs.

Figure 10: Trade Impact of the Euro, Europe, and EU: World As Control Notes: Panel (a) plots ever euro*year FEs (thus measures the euro effect over time) in a regression that also includes Western Europe*year FEs in the same regression. In panel (b), we compare the annual Euro dummies with annual Ever EU dummies (Ever EU*year interactive FEs), in the same regression as the EMU. The full data set is the control group.

Appendix Table 1: List of Switches Coterminous with a Hostile Colonial Separation

	Last Year	
Country-Pair	$of \ Event$	Description
1. United Kingdom-Zimbabwe of Colony	1964	Independence and Trade Sanctions; Rhodesian Bush War
2. France-Algeria	1962	War of Independence; Assasination; Military Consolidation of Govt.
3. France-Morocco	1956	Moroccan Independence following Anti-Colonial Rioting
4. France-Tunisia	1956	Tunisian Independence granted after separatist bombings
5. Portugal-Angola	1975	Angolan War for Independence followed by Civil War
6. Portugal-Cape Verde	1975	Cape Verde part of Guinea-Bissauan War of Independence
7. Portugal-Guinea-Bissau	1974	War for Independence; Marxist takeover, opposition slaughtered
8. Portugal-Mozambique	1975	War for Independence; Civil War
9. Portugal-Sao Tome and Principe	1975	Declared Independence following Coup in Portugal
10. Burma (Myanmar)-Pakistan	1970	Indo-Pakistani Wars; Myanmar expels 250,000 Muslims
11. Sri Lanka-India	1965	India-Pakistan war in 1965
12. India-Pakistan	1965	Border War, repeated conflicts thereafter
13. Algeria-Guadeloupe	1962	War of Independence; Assasination; Military Consolidation of Govt.
14. Guiana-Algeria	1962	War of Independence; Assasination; Military Consolidation of Govt.
15. Martinique-Algeria	1962	War of Independence; Assasination; Military Consolidation of Govt.
16. Algeria-Morocco	1956	Moroccan Independence following Anti-Colonial Rioting

18. Tunisia-Morocco	1956	Moroccan Independence following Anti-Colonial Rioting

6 Not for Publication Appendix

6.1 Using Country-Pair FEs Regression Framework Instead

The standard way to try to identify the CU effects is with a gravity equation in levels:

$$ln(T_{ijt}) = \gamma C U_{ijt} + \beta Z_{ijt} + \gamma_{ij} + \delta_t + \epsilon_{ijt}$$
(6.1)

where T_{ijt} is the average of bilateral imports and exports between country i and j at time t reported by both countries, CU_{ijt} is a 0/1 dummy for currency union status, γ_{ij} is a country-pair FE, δ_t is a year FE, and Z_{ijt} includes several other controls. These include bilateral log GDP, log GDP per capita, a dummy for regional trade agreements, and another dummy for current colonial status.

We modify this specification by introducing two new variables to control for countryyear-specific openness measures. The first control is the log of total exports for country i (minus country i's exports to j) plus total exports for country j (minus country j's exports to i). The second is the same measure, but for imports (country i's imports from all countries except for j). The idea is to control for general, year-specific measures of a country's trade costs, since we are interested in isolating the impact of currency unions only on specific country-pair trade. We also include controls for dummies for sovereignty of each country separately, which *a priori* could be expected to be a mild control, yet we find to be influential in some cases.

In Table 6 column (1), we replicate Table 2, column (4) of GR (2016). In the second column, we add in a number of intuitive controls, and also multi-way clustered errors, the latter of which only have a mild impact in this case. The additional controls include dummies for sovereign nations, and also total exports to the rest of the world (of both countries summed) and total imports from the rest of the world (of both countries summed; both figures are ex-bilateral trade). While these sound like mild controls, they have a dramatic impact on about half of the coefficients. The coefficient on Indian Rupee goes from 1.7 to 1.39, and the coefficient on "Other CUs" goes from 1.15, and highly significant, to just .73. The coefficient on East Caribbean CU goes from -.24 to -.85, and significant. In column (3), we exclude the CUs in which changes in CU status were coterminous with warfare or another significant geopolitical event. This kills the impact of the Indian Rupee, as it removes the CU between India and Pakistan. It also turned out that the dissolution of all three of the French CUs with countries that have GDP data happened to have been coterminous with warfare. Column (4) includes a number of intuitive controls, analogous to Table 3 column (3). In column (4), the only CU which is still significantly positive is the EMU. This is also true in column (5), when we additionally exclude the CUs in which switches in CU status are coterminous with missing data. In this case, the coefficient on the British pound is reduced to an imprecise -.17, quite distinct from the estimates we had in Table 3.

Figure 11 compares the evolution among future Euro countries to all Western European EU countries (adding Sweden, Denmark, and Great Britain), and to all countries in Western Europe (adding in Norway, Switzerland, and Iceland). The figure shows that there was a steady increase in trade integration in Western Europe from 1950 to 1990,

Table 6: How Robust is the CU Impact on Trade? (CPFE Regressions)

*p < 0.1, ** p < 0.05, *** p < 0.01. The dependent variable is the average of 4way log bilateral trade flows. Each regression includes country-pair and year fixed effects. In column (1), errors are clustered by country-pair in parentheses, and by country-pair and year from column (2). Column (1) replicates the results from Glick and Rose (2017), Table 2 column (4). Other controls, including GDP and GDP per capita, and dummies for regional trade agreement and currently a colony are omitted for space. Column (2) adds in multi-way clusters, and additional control variables, including total exports (ex-bilateral exports) for both countries, dummies for sovereignty. Column (3) excludes CU switches coterminous with warfare. Column (4) adds in the additional controls mentioned in the text. Column (5) excludes CU switches coterminous with missing data.

but that trade then plateaued, or even declined thereafter. The coefficient of -1 in 1970 means that countries that eventually joined the Euro traded about 63% less (=exp(-1)-1) than they did in 1998 (the last year prior to the Euro), relative to what would have been expected based on changes in GDP. Of course, if one ignores dynamics, and merely takes an average of trade before and after, then one would find that trade was vastly higher after the formation of the Euro. Yet, the timing of the increase in trade intensity – from 1950 to 1990 – does not suggest that the formation of the Euro was a driving factor.

The comparison with the EU and all of Western Europe makes for a slightly more optimistic picture of the Euro's effect on trade. The evolution of trade for Europe and the EU naturally look similar to the Euro, as these are largely the same countries (Iceland, Norway, and Switzerland are not in the EU, and the UK, Sweden, and Denmark are EU countries not in the Euro). However, trade among Euro countries has decreased slightly less (relatively) than trade between EU or all Western European countries. The caveats to this result are that the positive Euro effect here is too small to be statistically significant, and also that trade intensity among Euro countries had a slight positive pre-trend in the years before the formation of the Euro.

Figure 11: The Euro Impact vs. the EU, Europe

Notes: Panel (a) shows the evolution of the trade intensity of countries which eventually joined the Euro, vs. those that eventually joined the EU, and vs. all of Europe. *I.e.*, it plots annual gravity dummies from equation 2.1. The red bar denotes the last year prior to the formation of the Euro, 1999. All country-pairs with at least 40 observations are used as controls, and this exercise only includes non-Warsaw Pact countries. Panel (b) provides the same comparison, only using directional exports as the dependent variable, importer and exporter*year interactive FEs, from model 2.2.

An alternative approach is to note that since the most natural control group for Euro countries are other countries in Europe (or EU countries), if we re-run each of our models using only data for European countries (Figure 3, *i.e.*, we drop data for other continents from the regression), the picture looks less sanguine. We find that there is no more trade between Euro-Area countries relative to trade with the rest of Europe in 2013 as compared with 1998, the last year pre-euro, in either specification. In panel (b), in the version of the model with directional exports as the dependent variable, it actually appears that trade in Euro Area countries had declined slightly by 2013 relative to 1998. Of course, this amount is far from being statistically significant. This does raise another problem – our estimated standard errors are actually larger than what many people would find to be an intuitively plausible effect size. This makes it more likely than not that any significant measured effect will simply be spurious. Note that, even in this last specification, if we simply include a dummy for trade before and after the Euro, we will get a spurious positive result for the Euro, since trade did increase significantly in the Euro countries from 1950 to 1965. This increase was far too early to have been due to "anticipation effects". If we estimate from 1965 instead, the estimated effect will shrink (which we show in our panel regressions below).

(a) Model with CPFEs

(b) Model with Importer/Exporter*Year FEs

Figure 12: The Euro Effect by Year, with Europe as Control Group

Notes: Panel (a) shows the evolution of the trade intensity of countries which eventually joined the euro vs. the rest of Europe, using equation 2.1. All European countries with at least 40 observations are used as controls. Panel (b) uses the model with Importer/Exporter*Year FEs as in equation 2.2.

6.1.1 Additional Country-Pair Fixed Effects Regressions (online appendix)

Next, both for robustness, and for comparison with previous research, we run the following country-pair fixed effects (CPFE) regression:

$$ln(T_{ijt}) = \sum_{k=1}^{K} \alpha^k C U_{ijt}^k + \beta Z_{ijt} + \gamma_t + \delta_{ij} + \epsilon_{ijt}, \qquad (6.2)$$

where T_{ijt} is bilateral trade between country i and j at time t, CU_{ijt}^k is a 0/1 dummy for the status of currency union k between country i and j at time t, γ_t are year FEs, δ_{ij} are country-pair FEs, and Z_{ijt} are a number of other controls. These other controls include standard gravity arguments, including bilateral GDP, bilateral GDP per capita, total exports and imports of both country pairs (ex-bilateral trade), dummies for current colonial status, regional trade agreements, and also dummies for whether a country is a sovereign nation or not.

Next, in Table 7, we compare the country-pair fixed effects estimates on all currency unions aggregated together from various estimates in the literature, and our new estimates. In Glick and Rose (2002), the authors found a coefficient on currency unions of .65, implying a near doubling of trade, precisely estimated with a t-score of over 15. By contrast, Campbell (2013), using the same data, found that the coefficient fell to just .11, and imprecisely estimated, although he also finds a negative coefficient when controlling for country-pair specific trends.¹² Column (3) benchmarks the results from GR (2016), which greatly expanded the sample and again implied a doubling of trade. How-

^{12.} Note that, using the GR (2016) sample, we also find that including CU specific trends alone kills the results.

ever, when we exclude the war CUs and observations coterminous with missing data in column (4), and also include a number of intuitive controls (including UK Colony*year interactive FEs), the coefficient on currency unions falls to just .11, and once again imprecisely estimated. When we separate the effect into the EMU vs. the non-EMU CUs, once again the GR (2016) results benchmarked in column (5) are not robust in column (6) when we omit the war CUs and add other controls in column (6). While it might seem a suggestive coincidence that both columns (2) and (4) imply a still-large impact of currency unions on trade close to 11%, neither are precisely estimated, while Campbell (2013) also found that including trend controls yield an impact of -5%, while Table 3 yields an estimate of 5%. Clearly, these are noisy estimates which are likely to be influenced further by additional controls.

 Table 7: The Currency Union Effect over Time: Booms and Busts

	(1)	(2)	(3)	(4)	(5)	(6)

p < 0.1, p < 0.05, p < 0.01. Each regression includes country-pair FEs (CPFEs). Column (1) benchmarks the baseline estimate from GR (2002), absent year FEs. Column (2) benchmarks the results (absent trend controls) from Campbell (2013), and includes year FEs. Columns (3) and (5) benchmark the CPFE results from GR (2016). Columns (4) and (6) omit the CUs in which switches were coterminous with war or missing data, and also includes other intuitive controls.

6.2 Additional Results for the Euro (Online Appendix)

6.2.1 Additional Euro Results: Limiting the Sample to Northern Europe

Most of the control countries for the Euro - i.e., countries that are in the EU but not in the Euro, or countries that are in Western Europe but not in the EU, are actually located in Northern Europe. Thus, the more comparable portion of the treatment group for this particular control group would actually be other Northern European countries that are in the Euro. Thus, we repeat the exercise we did above in Figure 12, only comparing the evolution of trade between Euro countries, EU countries, and all countries in Western Europe while limiting ourselves only to countries in Northwest Europe (thus, we exclude Portugal, Spain, Italy, Greece, Cyprus, and Malta from this analysis). The results are

presented in Figure 13. In this case, it does look as though Euro countries slightly outperformed other countries in NW Europe after the formation of the Euro, although the difference is not statistically different. The differences with Figure 3 in the main paper are slight, which is why we relegate this version to the Online Appendix.

Figure 13: The Euro Impact vs. the EU, Northwest Europe

Notes: This graph shows the evolution of the export intensity of countries in Northwest Europe which eventually joined the Euro, vs. those that eventually joined the EU, and vs. all of Northwest Europe (we exclude Portugal, Spain, Italy, Greece, Cyprus, and Malta from this analysis). *I.e.*, it plots annual gravity dummies from equation 2.1. The red bar denotes the last year prior to the formation of the Euro, 1999. All country-pairs with at least 40 observations are used as controls, and this exercise only includes non-Warsaw Pact countries.

6.2.2 Additional Panel Regression Results for the Euro

Next, we move to a panel regression approach so that we can definitively answer whether the Euro effect is statistically significant pooled across years, and report the results in Table 8. In this table, we use equation 6.1 (using bilateral trade as the dependent variable) in the first three columns and equation 2.2 (which uses directional exports instead), in the following four columns. In column (1), we benchmark the results from GR (2016). In column (2), we add in EU*Year and Eastern Europe-Euro Area*Year interactive fixed effects, using the same control group as in Figure 4. We also add in multi-way clusters. When we do this, the impact of the Euro is approximately cut in half, and the standard errors increase slightly. In column (3), we limit the control group to Western Europe, and also include a simple time trend control and limit the period to after 1975 when the trend starts, as is implied by Figure 12(a). We find that this trend control eliminates the significance of the Euro.

Next, in column (4) we use the model with unilateral exports, and replicate the results from GR (2016), Table 5 column 5, only adding in multi-way clusters, by both country-pair and year. This alone reduces the t-score by 75% (GR reported errors of

Dep.Variable	Bil.Trade	Bil.Trade	Bil.Trade	Exports	Exports	Exports	Exports
Sample	World	World	W.Europe	World	World	W.Europe	W.Europe

Table 8: How Robust is the Euro Effect on Trade?

*p < 0.1, **p < 0.05, ***p < 0.01. The dependent variable in the first three columns is the average of 4-way log bilateral trade flows, and in the last four columns it is the average of exports from country 1 to 2 reported by country 1 and reported by country 2. The first three columns include country-pair and year fixed effects, while the last four columns include Importer*year, Exporter*year, and country-pair FEs. In column (1), errors are clustered by country-pair in parentheses, and by country-pair and year from column (2). Column (1) replicates the results from Glick and Rose (2016), Table 2 column (4). Other controls, including GDP and GDP per capita, and dummies for regional trade agreement and currently a colony are omitted for space. Columns (2) and (5) add EU*year and EE-Euro Area*Year interactive FEs. Columns (3), (6), and (7) limit the control group to Western Europe. Columns (3) includes a control variable for trends in trade for countries that eventually joined the Euro. Columns (3) and (7) limit the sample to the post-1975 and post-1965 periods, respectively.

.02 vs. .083). When we add in the same EU*Year and Eastern Europe-Euro Area*Year interactive controls as in column (2), we get a point estimate of .055 (roughly 5%), but with a standard error of .069. In column (6), we limit the sample and control group to Western Europe (and drop the controls). This time we get a point estimate of 12%, although not significant. In column (7), following the logic learned from plotting our data in Figure 12(b), we limit the sample to the post-1965 period, and find that that the point estimate shrinks to just 3%, again imprecisely estimated.

To conclude, in this section we found that the Euro impact on trade is sensitive to the control group chosen, and can thus be eliminated even without including time trends. We conclude from all these exercises that the Euro Effect on trade is not robust, and that earlier large positive impacts conflated the Euro with the long history of European trade integration, the EU, and the collapse of the Soviet Union and the opening of Eastern Europe to trade. And since the Euro observations constitute 29% of all the CU switches with time series variation, we believe this section alone casts significant doubt on the overall "currency union effect".

6.2.3 Did the Euro Increase Trade with non-Euro Members?

In the main part of the paper, we tested whether trade between Euro countries increased relative to trade between trading pairs where one country was in the Euro and one was not. However, the Euro might also have raised trade generally. Thus, here we test first whether the Euro increased overall trade, and secondly, whether currency unions in general increase trade-to-GDP ratios. We propose a simple model:

$$ln(X_{it}/GDP_{it}) = \alpha Euro_{it} + \alpha_i + \gamma_t + \epsilon_{ijt}, \qquad (6.3)$$

a regression of annual dummies for all Western European countries that joined the Euro, with controlling for country and year dummies. The sample is all countries in the world that have both World Bank GDP data and IMF DOTS trade data. The annual dummies with two standard deviation errors are plotted in Figure 14. In panel (a), it can be seen that while trade over GDP rose strongly in Euro Area countries until the early 1990s, since 2005 this intensity has fallen. This could be for many factors unrelated to the Euro, such as relatively rising trade integration in other parts of the world, or to the growth slowdown which may have lowered trade more than one-for-one.

(a) Euro Countries

(b) Euro Countries vs. all of Europe

Figure 14: The Impact of the Euro on Total Trade/GDP

Notes: Panel (a) shows the average trade/GDP relative to 1998 of Western European countries (not Warsaw Pact countries in Europe) with 2-standard deviation error bounds. Panel (b) compares future Euro countries to all of Western Europe. E.g., this sample adds in the UK, Iceland, Sweden, Switzerland, Norway, and Denmark to the sample of Western European Euro countries.

6.3 UK Currency Unions

In GR (2002), 26 of the 136 CU switches in the sample involved the UK. In GR (2016), slightly over a third (150 of 408 of the bilateral pairs) of the CU switches involve the British Pound.

In this case, since most country-pairs with time series variation in CU status exhibit just one change in status, a dissolution, a panel regression in levels with no controls for trends could be prone to finding correlations even when a true relationship does not exist. The basic problem can be seen in Figure 15(a) below when we compare the evolution of trade between the UK and its former colonies vs. the UK and countries with which it used to share currency unions with (adding yearly dummies to equation 6.1).¹³ There is a lot of overlap between the two, as all but one country that shared former currency unions with the UK in this sample were also former colonies, while nearly half of the former colonies had currency unions (30 of 67). The trend for each is negative, consistent with the gradual decaying of former colonial trade ties as stressed by Eichengreen and Irwin (1998), Head et al. (2010), Head and Mayer (2013) and Campbell (2010). In addition, many of the currency unions were dissolved during the Sterling Crisis in the late 1960s. Thus, if one naively takes an average of trade in the 1950 to 1968 period, and compares it with trade thereafter, one will conclude that the currency union dissolution caused the decline in trade. If one includes a simple trend for UK trade with its former colonies, by contrast, one will not find a correlation between CUs and trade.

(a) Evolution of UK Trade with Colonies vs. CUs (b) All Pound CUs (Dir. Export Specification)

Figure 15: Trade and the Pound

Notes: Panel (a) plots the evolution of gravity dummies over time between the UK and its former colonies, compared to the evolution of trade between the UK and countries with which it shared a currency union (from a gravity regression with only time FEs). Panel (a) is from a model with bilateral trade as the dependent variable and includes year and CPFEs. Panel (b) includes all Pound CUs (including those not involving the UK), and uses the model with directional exports as the dependent variable and includes importer-year and exporter-year fixed effects (and thus has many more observations). Panel (a) uses just the original GR (2002) data. The net decline in CUs each year is a bar chart with magnitude on the left axis. A coefficient near unity in 1997 indicates that trade was (=exp(1)-1) approximately 170% larger than one would otherwise expect.

However, with this new, much larger data set, many of the observations of countries which used the pound did not necessarily involve the UK. Running the second version of our model with directional exports as in equation 2.2 in Figure 15(b) on all UK CUs, we find that trade did decline after, although the decline in trade happened much later, starting in the late 1980s, while most of the dissolutions happened in the late 1960s. Thus, the timing appears suspicious.

^{13.} Indeed, both of the lines plotted come from Campbell (2013), who claimed to have "solved" the Glick and Rose puzzle.

Next, we run panel regressions in Table 9, using the regression in equation 2.2 for the first three columns and the model in 6.1 in the last two columns. We separate out the Pound CUs involving the UK from the others. In column (2), we add in UK-UK Colony*Year FEs, and another set of annual FEs when both countries are UK colonies, and the coefficients on both UK CUs and other Pound CUs both shrink moderately. Next, we limit the sample to the pre-1990 period, as suggested by Figure 15(b), and find that the UK CUs are no longer significant. Turning to the model using bilateral trade as the dependent variable (equation 6.1), we find that the Pound increased trade among those who used it by 153% (=exp(.93)-1). If true, this would imply that adopting the Pound might have quite large effects for not just trade, but also for welfare, growth, and development. However, when we include the same controls as we did in column (2) (with the results in column 5), UCs now appear to *reduce* trade by a sizeable 17%, although imprecisely estimated. The non-UK Pound CUs admittedly provide the best evidence for the CU effect, although, as we see, the significance of these depends on the specification.

Table 9: British Pound Currency Unions and Trade: How Robust?

	(1)	(2)	(3)	(4)	(5)

Observations	877736	871392	368103	426507	372625
Dep.Var.	Exports	Exports	Exports	Trade	Trade

*p < 0.1, ** p < 0.05, *** p < 0.01. The dependent variable in the first three regressions is log exports, and is log trade in the last two columns. The first three columns include Importer*Year, Exporter*Year, and Country-Pair FEs. The last two columns include country-pair and year FEs. Column (1) reproduces the specification from GR (2016), Table 5 (equation 2.2). Column (2) adds in controls as described in the text. Column (3) additionally limits the sample to the pre-1990 period. Column (4) uses equation 6.1, and benchmarks GR (2016), Table 2. Column (5) adds in the same controls as columns (2) and (3).

6.4 The Rupee Zone

Next, we turn our attention to the Indian Rupee zone. As mentioned in the introduction, this is another example of a CU effect perhaps driven by endogeneity. This is true not just for India and Pakistan, which fought a war in 1965, which also likely effected trade between Pakistan and Sri Lanka. Bangladesh and India ended their currency union in 1973, just following the Bangladesh Atrocities, after which 10 million Bengalis took

refuge in India. These massive political events likely overshadowed the impact of a change in currency union status.

Our first exercise is to plot a yearly dummy variable for country pairs which had ever shared the Rupee in Figure 16(a) (analogous to equation 2.1). We find a negative trend in trade from the early 1950s to 1965, when several Rupee unions first dissolved (the other two dissolved in 1969 and 1971). Again, this is something of a counterexample, as it implies that trade declines during currency unions. However, when we exclude the observations involving war in panel (b), the pre-trend becomes much less prominent, particularly relative to large standard errors. Indeed, in panel (b), it appears there is no discernable effect of leaving the Rupee, although if anything, trade appeared to be slightly higher in many years after dissolution relative to the last year before the Rupee union unwound.

(a) Impact of Leaving the Rupee

(b) Excluding War

Figure 16: The Rupee Zone

Notes: Panel (a) shows the evolution of the trade intensity of countries over time which shared the Rupee. The vertical red line indicates the dissolution of four of these unions, with two others dissolving in 1969 and 1973. Panel (b) excludes India and Pakistan.

6.5 The CFA Franc Zone

When we look at data for the CFA Franc Zone, we see a potential role for missing data in helping to explain "the Rose Effect". We plot the evolution of trade between Comoros and Cameroon, who dissolved their currency union in 1993, vs. Comoros and Nigeria, the latter of which was never part of the CFA in Figure 17(a). After the dissolution, trade was lower on average. However, trade between Comoros and Nigeria also fell, despite no CU dissolution. Next, in panel (b), we break up trade for Comoros and Cameroon into imports and exports. We see that, in fact, Comorian imports actually increased after dissolution – another counterexample – but that exports were only recorded after dissolution. These were always at a lower level than the one import reading available before dissolution. Thus, there is a reason to be concerned that missing data might be

	GR Benchmark	Cluster

		(0.31)
Observations	877736	877736

Table 10: Checking the Rupee Effect

 $p^* < 0.1, p^* < 0.05, p^* < 0.01$. The dependent variable in the first three columns is the average of 4-way log bilateral trade flows, and in the last four columns it is the average of exports from country 1 to 2 reported by country 1 and reported by country 2. The first three columns include country-pair and year fixed effects, while the last four columns include Importer*year, Exporter*year, and country-pair FEs. In column (1), errors are clustered by country-pair in parentheses, and by country-pair and year from column (2). Column (1) replicates the results from Glick and Rose (2016), Table 2 column (4). Other controls, including GDP and GDP per capita, and dummies for regional trade agreement and currently a colony are omitted for space. Columns (2) and (5) add EU*year and EE-Euro Area*Year interactive FEs. Columns (3), (6), and (7) limit the control group to Western Europe. Columns (3) includes a control variable for trends in trade for countries that eventually joined the Euro. Columns (3) and (7) limit the sample to the post-1975 and post-1965 periods, respectively.

driving the apparent large impact of the CFA Franc on trade as well.

Next we plot the evolution of CFA Franc trade before and after dissolution (Figure 18(a)), and entrance (Figure 18(b)).¹⁴ We find, once again, that the timing of the trade collapse in the case of exits is a bit odd. There is a significant, and massive, decline in trade from 15 to 5 years before dissolution. After that, trade was relatively flat before and after dissolution. The timing of the trade decline, and subsequent recovery post-dissolution, suggests that the CFA constitutes another counterexample, even though a naive dummy variable regression ignoring dynamics will find that trade flows were significantly higher in the pre-dissolution period. The trade dynamics for entrants in panel (b), on the other hand, admittedly does provide suggestive evidence for the proposition that currency unions increase trade. However, even then, the dynamics look questionable, as bilateral trade was roughly the same 15 years after the CU as it was before.

Next, in Table 11, we test the impact of the CFA Franc using a panel data regression approach as in 6.1. In column (1), we benchmark the results in Table 2 column (4) of GR (2016). In column (2), we exclude the trade collapse that took place more than 5 years before the end of CUs, effectively comparing trade in the last 5 years of a CFA Franc relationship to the period after. The coefficient shrinks to .29 with a standard error of .34 and is thus insignificant. In column (3), we limit the control group to Africa, and

^{14.} Once again, here we are using model 2.1.

Figure 17: Missing Data Drive the "Collapse" in Trade

Notes: Panel (a) shows the evolution of the trade between Comoros and Cameroon, who ended their CU in 1993, vs. a control group of Comoros and Nigeria. In panel (b), we disaggregate Comoros-Cameroon trade into imports and exports. We see that Comorian imports actually rose after dissolution, and that there is no Comorian export data before.

Figure 18: Impact of CFA Exits and Entrances

Notes: Panel (a) shows the evolution of trade before and after exits into the CFA Franc using equation 2.1. Panel (b) shows the evolution of trade before and after entrances.

include separate dummies for the CUs more than 5 years before dissolution, and again find insignificant results. In column (4), we exclude observations where either import or export data is missing. In fact, in this case, the coefficient actually increases slightly, although so does the standard error. In column (5), we add in Africa*Year FEs instead. In column (6), we use the second model (equation 2.2) with exports as the dependent variable, and include our separate dummies for the CFA observations more than 5 years before dissolution. In column (7), we additionally limit the sample to Africa. The main message here is that, while we do not necessarily have a favorite specification, the original estimates of .89 and .72 is not robust, even if the point estimate is still large.

Table 11: The CFA Franc and Trade: How Robust?

*p < 0.1, **p < 0.05, ***p < 0.01. The first five columns include country-pair and year fixed effects. Column (1) includes errors clustered by country-pair, and columns 2-5 include errors clustered by country-pair and year. Columns (6) and (7) include errors clustered by country-pair. Column (1) replicated Table 2 column (4) from GR (2016). Other controls, including GDP, GDPPC, and dummies for RTAs and Currently a Colony are omitted for space. In column (2), we added in controls for total exports and imports (ex-bilateral trade).

6.6 The Demise of French and Portuguese Currency Unions

In our sample, France had two currency unions with time-series variation in the data, and Portugal had five. However, in all of these cases, the end of these currency unions was coterminous with often violent wars for independence. The tamest of these was Morocco, where independence was granted following widespread anti-colonial rioting. Each of Portugal's colonies that shared currency unions – Angola, Cape Verde, Guinea-Bissau, Mozambique, and Sao Tome and Principe – had to fight for their independence. In Guinea-Bissau, the war for independence ended with a Marxist takeover in which the opposition was slaughtered. It is simply unimaginable that, in cases like this, the currency had a large negative effect on trade, but that a communist takeover of the government did not affect trade at all. Thus, in our panel regression results in the next section, we will test whether the results are sensitive to dropping this sample.

6.7 US Dollar-based Currency Unions

We begin by plotting the pretreatment and post-treatment trends of exiting and entering dollar unions in Figure 19. The graphs are created by re-running equation 2.1 on annual dummies indicating how many years before or after a change in CU status. What we see is that, reassuringly, there is not much of a long-term "pre-treatment trend" before exits, although trade did fall a lot in the last year of the currency union. However, after exit, within 5 years, country-pairs on the dollar traded significantly more than in the last year prior to exit. Thus, dollar exits appear to foster trade (spurious, in our view) but nevertheless constitute a counterexample.

Figure 19: The Effect of Dollar Entrants and Exits

Notes: Panel (a) shows the evolution of the trade intensity of countries which eventually exited the dollar, using equation 2.2. Panel (b) shows the evolution of gravity dummies for the sample of countries that began using the dollar.

The entrances do not tend to show much, although there appears to have been trade collapses about five years prior to entry. Indeed, on the whole, even Glick and Rose do not find that US Dollar CUs increase trade. Once again, we would argue that this result is another reason to doubt a large CU effect in other settings.

6.8 Australia CUs

Australia shared currencies unions with several small Pacific islands. Thus, we begin by simply plotting trade for several of these islands to try to understand the factors which might be driving the results. Figure 21(a) plots trade between Kiribati and Tonga, who exited a currency union in 1990, and compare it to trade between Kiribati and Fiji, which were never in a currency union. Indeed, we see that trade between Kiribati and Tonga was much lower in the year of dissolution and thereafter, even relative to the "control" of Kiribati and Fiji, matching the theory of Glick and Rose. However, in Figure 21(b), when we separate out imports to Kiribati from Tonga vs. exports, we see that this ostensible trade collapse was driven by missing data. There are only four readings for Kiribati imports from Tonga in the data set, and each one reports similar values. The results are drive by exports from Kiribati to Fiji only being recorded for the date pre-dissolution. Each time they were recorded, they were at a much higher level than imports.

Next, we repeat the exercise we did for the US, and plot annual indicator dummies for years before leaving an Aussie CU (there are no entrants) in Figure 22(a). While we

(a) Gravity Dummies on Intra-Euro Area Trade

(b) vs. Europe and EU

Figure 20: Assessing the Euro Impact by Year

Notes: Panel (a) shows the evolution of the trade intensity of countries which eventually joined the euro. The red bar denotes the year the Euro was formed, 1999. *I.e.*, it plots annual gravity dummies from equation 2.1. All country-pairs with at least 40 observations are used as controls. Panel (b) compares this measure to gravity dummies for all European countries, and countries which would eventually join the EU.

(a) Kiribati-Tonga Trade (vs. Fiji)

(b) Kiribati-Tonga Trade

Figure 21: Missing Data Drive "Collapse" in Kiribati-Tonga Trade

Notes: Panel (a) shows the evolution of the trade between Kiribati and Tonga vs. Kiribati and Fiji. Kiribati and Tonga ended their currency union in 1990. After, trade was lower. Kiribati-Fiji might be a good control, but its data is missing in 1990 and 1991. In panel (b), we disaggregate Kiribati-Tonga trade into imports and exports. There were no years in which both exports and import data was recorded.

Table 12: Impact of the Euro: Post-1990 Data Only

	(1)	(2)	(3)	(4)
	GR, CPFE	+Controls	GR, I/M*Year FEs	+Controls

Observations	252877	223636	489298	489298

 $p^* < 0.1, p^* < 0.05, p^* < 0.01$. The dependent variable is the average of 4-way log bilateral trade flows. Each regression includes country-pair and year fixed effects. Column (1) reproduces the results from GR (2002). Column (2) reproduces the results from Campbell (2014). Column (3) replicates the results from Glick and Rose (2017), Table 2 column (4). Column (4) includes the controls, data adjustments, and multi-way clusteres from the previous table. Other controls, including GDP and GDP per capita, and dummies for regional trade agreement and currently a colony are omitted for space. Column (2) adds in multi-way clusters, and additional control variables, including total exports (ex-bilateral exports) for both countries, for countryseparating GDP by country 1 and country 2, and . Columns (2), (5), and (6) include controls for country-pair trends for countries with time series variation in CU status. EMU = EuropeanMonetary Union. "CUs, Ex-War, Missing" means Currency Unions in which the changes are not associated with war or some other major geopolitical event or missing data.

see little action after dissolution, there happens to be a trade collapse during the CU period starting about 10 years prior to dissolution, which culminates in the year before dissolution. After dissolution, trade stabilizes. Thus, once again, Australian CUs appear to be another counter-example, and one in which a simple dummy strategy in a panel regression in levels will provide misleading inference.

Thinking about an appropriate control group for Australian CUs, and obvious control country could be New Zealand. Thus, in Figure 22(b), we run the same regression only limiting the control group to all countries that ever used the Australian dollar plus their trade with New Zealand. This time, the trade collapse ten years prior to dissolution is much less pronounced, and is no longer statistically significant.

Lastly, we run a few panel regressions based on equation 6.1. In column (1), we replicate the GR (2016) benchmark from their Table (2), column (4). In column (2), we simply restrict the Kiribati-Tonga trade to Kiribati imports, since we have this data recorded before and after dissolution. This small change alone shrinks the magnitude of the impact by about 6%, and also increases the error by about 3%. In column (3), we add in several other mild controls, the log of total exports for each country (ex-bilateral trade), and total imports (also ex-bilateral trade). These mild controls further reduce the coefficient by another 8%, at which the coefficient on Australian currency unions is only significant at 10%. In column (4), we add in country*year interactive FEs for each of the countries that have Aussie CUs – Australia, Tonga, the Solomon Islands, and Kiribati. This time, we get a negative coefficient, albeit with large standard errors. Finally, in column (5), we create a matching sample, limiting to these countries trade between each other and New Zealand. Now the estimate returns to a fairly large 20%,

Figure 22: Australian Currency Unions

Notes: Panel (a) shows the evolution of the trade intensity of countries which had currency unions with Australia (Tuvalu, Tonga, and Kiribati) after separation, using equation 2.2, and using the full sample as controls. Panel (b) looks uses these countries' trade with New Zealand as the main control.

albeit once again imprecisely estimated.

Table 13: Australian Currency Unions and Trade: How Robust?

p < 0.1, p < 0.05, p < 0.05, p < 0.01. Each regression includes country-pair fixed effects, and errors clustered by country-pair in parentheses. Other controls, including GDP and year FEs omitted for space. Columns (2) and (3) substitutes Kiribati log imports from Tonga in place of total trade. Column (3) uses trade between the Solomon Islands and Tonga with New Zealand as the matching control group.

6.9 Additional Results on Dynamics

On the whole, figure 25 does not necessarily imply a pressing need to take a dynamic approach, as excluding the CUs coternminous with wars and missing data, and adding in other controls mostly eliminated the pre-treatment trends. On the other hand, panel (b) suggests this might be advisable. Thus, next we show our main result – that the impact of CUs on trade is not statistically significant – holds up even when we add in a lagged dependent variable. We do this for both the GR specification in Column (1) in Tables 3 and 6, and to our preferred specification in Column (6) of the same tables, which excludes the CU switches coterminous with wars and missing data, and adds in controls such as the "Ever EU*Year" interactive FE. Thus, in column (1) of Table 17,

we add in lagged log bilateral trade as a control variable to the regression in equation 6.1. Of course, since this equation also includes fixed effects, this will induce Nickell Bias (Nickell (1981)). However, Nickell showed that this bias will be small in a long panel. Thus, we limit to panels with T>40, which happens to make no difference to the key coefficients, but gives us an average panel of 50 years, long enough to provide an upper bound on the bias which is relatively small.¹⁵. In column (1), a coefficient of .21 implies a long-run impact of 56% (=.21/(1-.63)). In column (2), however, when we add in our controls and exclude the War CUs and those with missing data, we get an impact of 8.3% (=.024/(1-.71)), although not statistically significant. Columns (3) and (4), which use the directional exports instead of bilateral trade as the dependent variable, and which also control for Importer*Year and Exporter*Year FEs, points to similar conclusions: the effect of CUs on trade is not robust.

*p < 0.1, ** p < 0.05, *** p < 0.01. The dependent variable in the first two columns is log bilateral trade and log directional exports in the last two columns. The first two columns include country-pair and year FEs, and the latter two add Importer and Exporter*year FEs. Column (1) adds in a lagged dependent variable to the GR (2016), Table 2 specification. Column (2) adds in a number of controls, and limits the CU observations to those ex-War and missing. Column (3) adds in a LDV to the specification in Table 5 of GR (2016). Column (4) adds in in a number of controls, and limits the CU observations to those ex-War and missing.

6.10 A Systematic Control for War (Online Appendix)

6.11 Additional Plots of Trade (Online Appendix)

Figure 24(b) shows the evolution of bilateral trade between Sri Lanka and Mauritius. This highlights two related problems: first, while trade was generally lower after the 1966 currency union dissolution, there was no trade recorded for the entire 1960s. Secondly, the trade data pre-dissolution which does exist suggests that trade had been plunging for

^{15.} For reasonably large values of T, the formula for the bias is approximately $\frac{-(1+\rho)}{(T-1)}$. In this case, the bias is approximately -1.63/49 = .033.

Table 17: Dynamic Models III

*p < 0.1, **p < 0.05, ***p < 0.01. The dependent variable in the first two columns is bilateral trade, the log change in bilateral trade in the third column, log bilateral exports in columns (3) and (4), and the log change in bilateral exports in column (6). Each regression includes country-pair FEs (CPFEs). Column (1) benchmarks the baseline estimate from GR (2002), absent year FEs. Column (2) benchmarks the results (absent trend controls) from Campbell (2013), and includes year FEs. Columns (3) and (5) benchmark the CPFE results from GR (2016). Columns (4) and (6) omit the CUs in which switches were coterminous with war or missing data, and also includes other intuitive controls.

Figure 23: Impact of the "Correlates of War" Dummy on Trade

Notes: This figure plots leads and lags of a dummy for two countries being in a war with each other. The dummy when entered itself in a panel regression. It's likely because occasionally one country is occupying part of the other country, either during, or after the war ends.

Figure 24: The Rupee Zone

Notes: Panel (a) shows the evolution of the trade intensity of countries over time which shared the Rupee. The vertical red line indicates the dissolution of four of these unions, with two others dissolving in 1969 and 1973. Panel (b) looks uses these countries' trade with New Zealand as the main control.

Table 19: PPML estimation

p < 0.1, p < 0.05, p < 0.05, p < 0.01. The dependent variable is unilateral exports, averaged from Importer and Exporter reports. Each regression includes country-pair FEs and Exporter/Importer time fixed effects. Column (1) benchmarks the estimate from Glick and Rose (2016) Table 5, column (6). In column (2) we apply three-way clustered standard errors to the results of column (1). In column (3) we omit the CUs in which switches were coterminous with war or missing data. Column (4) adds intuitive control variables to the specification of column (3). Columns (5) and (6) provide the results of specification (4) for more aggregated CUs.

Table 20: Multi-Way Clustering

p < 0.1, p < 0.05, p < 0.05, p < 0.01. The dependent variable is unilateral exports, averaged from Importer and Exporter reports. Each regression includes country-pair FEs and Exporter/Importer time fixed effects. Column (1) runs the Glick and Rose (2016) Table 5, column (6) benchmark, only with country-pair clustered standard errors. In column (2), we cluster by country-pair, and year. In column (3), we cluster by importer, exporter, and year. In Column (4), we include our full set of controls detailed in section 2.3. In column (5), we cluster by country-pair and year in our regression with the controls. In column (6), we cluster by importer, exporter, and year, in a regression with controls.

Table 22: Previous Master Regression Table (Dec. 2018 Version)

*p < 0.1, **p < 0.05, ***p < 0.01. The dependent variable is unilateral exports, averaged from Importer and Exporter reports. Each regression includes country-pair FEs and Exporter/Importer time fixed effects, and errors clustered at the country-pair level. Column (1) runs our Table 3, column (2) specification. Column (2) adds in a dummy for colonial relationships that did not end well. Column (3) adds in a time trend for CFA Franc exits. Column (4) adds in the UK colony*year dummies and common UK colonizer*year trends. Column (5) adds in a dynamic EU control. Column (6) adds in the Eastern Europe*Western European EMU*year interactive FEs.

6.14 Synthetic Control Method (Not-for-Publication Appendix)

Following Saia (2017), who finds that the UK trade with Euro Zone countries would have been 16% higher had they adopted the Euro, we also try a synthetic control approach. To build a matrix of weights for a control group, Saia uses the the following variables: "the values of bilateral trade flows and the sum of the logs of country pair GDPs averaged over the period 1980-1998, plus three endogenous variables $BVDIST_{ij}$, $BVADJ_{ij}$. and BVLANG..."

While Saia (2017) deserves credit for applying this innovative approach to this particular literature, there are several difficulties in applying this approach to our full sample, and other adjustments one might to make. First, the magnitude of nominal trade is one of the main variables used to create the control group, but this is not even in logs, and there is little reason to think that just because two groups of (potentially unrelated) countries have the same nominal trade magnitudes, that trade will evolve similarly. There is no control for growth in trade, for example. Similarly, GDP is also in raw magnitude, and not even on a per capita basis. Thus, other countries that happen to be the same size will tend to be in the control group, rather than countries with similar trade-to-GDP ratios, for example, or who trade with similar countries.

Thus, as a proxy for UK-Portuguese trade, the country pairs that wind up in the control group are (a) far apart, and (b) have little trade, as Portugal is the smallest country in Saia's 9 country EMU sample. Intuitively, one might think Portugal-Netherlands, Portugal-Belgium, Portugal-Germany, and Portugal-Finland would be the control-group country-pairs with the most predictive values for "trade as a fraction of GDP". Yet, Saia does not include "country FEs" in the selection criteria, so Portugal's trade with other countries is not more likely than trade with any other country to predict Portuguese trade with the UK. Instead, the algorithm assigns a 48% weight to Spain-Finland (GDPs and trade similar to the UK-Portugal, and are far apart), a 22% weight to Austria-Italy (once again, this appears mostly to be about magnitude), and all the Portuguese country-pairs combined receive a weight of just 5.8%.

We repeat Saia's method, only, when we create our counterfactual, we: (1) Use $\ln(\exp orts12/gdp1^*gdp2)$ – directional exports over bilateral GDP as the dependent variable. This effectively controls for GDP growth in both trading partners. (2) Include in the weights, a dummy for the 2nd country in the pair. *E.g.*, For the British share of exports to Portugal, we want other countries' exports to Portugal to receive a greater weight. This is because there might be Portugal-specific shocks to hit in a given year. (3) Instead of matching on the magnitude of trade, we also match on the growth in trade in the beginning and end of the pre-treatment period. This effectively controls for trends in trade. (4) We also want to control for British trade with the rest of the world. It might just be that British trade increased slowly after 1999 for reasons unrelated with the Euro. This possibility is effectively not controlled for by Saia. To do this, we run a regression controlling for total trade (with the world outside of our sample, and using just country-pair and year dummies), and then we use the residuals from this regression to create synthetic controls. This effectively controls for trends in total British trade.

First, we are able to match Saia's results. Secondly, in our robustness, we find that, eight years after the formation of the Euro, UK trade would have actually been less as

a share of GDP had the UK joined the Euro. After that, the synthetic control takes over, but by the end of the sample, there is only a slight difference (.9%) between the two series, unlikely to be statistically significant.

Figure 25: Did the UK Miss Out? A Sythetic Control Approach

Notes: Panel (a) replicates Saia (2017). The dotted line represents actual UK trade with the Euro Zone, while the blue represents trade from a synthetic control group using only trade within Euro Zone members. Panel (b) uses trade over bilateral GDPs as the dependent variable, chooses a control group using growth, and includes a "country 2 dummy" in the selection criteria.
